On the magnitude of spheres, surfaces and other homogeneous spaces

Simon Willerton

May 2010

Abstract

In this paper we define the magnitude of metric spaces using measures rather than finite subsets as had been done previously and show that this agrees with earlier results. An explicit formula for the magnitude of an n-sphere with its intrinsic metric is given. For an arbitrary homogeneous Riemannian manifold the leading terms of the asymptotic expansion of the magnitude are calculated and expressed in terms of the volume and total scalar curvature of the manifold. In the particular case of a homogeneous surface the form of the asymptotics can be given exactly up to vanishing terms and this involves just the area and Euler characteristic in the way conjectured for subsets of Euclidean space in previous work.

Introduction

The magnitude of finite metric spaces is a partially defined numerical invariant which was introduced by Leinster via a category theoretic analogue of the Euler characteristic of spaces, group and posets. If a finite metric space is scaled up sufficiently then the magnitude tends upwards to the number of points in the metric space and, typically, as the metric space is scaled down the magnitude tends to one; this allows one to think of the magnitude as the 'effective number of points' in the metric space. Interestingly, magnitude has applications in measuring biodiversity (see [10] and [4]).

In previous papers [6] and [11] we speculatively studied the magnitude of *infinite* metric spaces using finite subsets as approximations. Whilst we do not know that the magnitude can always be defined in that way it seems to give meaningful answers for many subsets of Euclidean space, both numerically and theoretically. For instance, in [6] it is shown using that approach that a closed, bounded subinterval of the real line can be assigned a magnitude equal to one plus half its length; similarly magnitudes can be assigned to circles and to Cantor sets. (These results are corroborated here in Section 1 using the measure theoretic approach of this paper). In [11] the magnitudes of various simple subsets of $\mathbb{R}^2$ and $\mathbb{R}^3$ were calculated numerically and for various spaces considered it was observed that if the metric space was scaled up then the magnitude seemed to asymptotically depend on classical intrinsic volumes of the space such as volume and Euler characteristic. For *convex* sets it appeared that this dependence held even non-asymptotically, so for a square it seems, numerically at least, that the magnitude is given by $\frac{1}{2\pi}\mathrm{area} + \frac{1}{4}\mathrm{perimeter} + 1$.

In this paper we look at the magnitude of homogeneous Riemannian manifolds, using a measure theoretic approach rather than the finite subset approach mentioned above. The magnitude is calculated explicitly for the n-sphere of radius R with its intrinsic metric, leading to the following answer.

$$|S^n_R| = \begin{cases} \dfrac{2\Big(\big(\frac{R}{n-1}\big)^2+1\Big)\Big(\big(\frac{R}{n-3}\big)^2+1\Big)\dots\Big(\big(\frac{R}{1}\big)^2+1\Big)}{1+e^{-\pi R}} & \text{for } n \text{ even} \\[2ex] \dfrac{\pi R\Big(\big(\frac{R}{n-1}\big)^2+1\Big)\Big)\Big(\big(\frac{R}{n-3}\big)^2+1\Big)\dots\Big(\big(\frac{R}{2}\big)^2+1\Big)}{1-e^{-\pi R}} & \text{for } n \text{ odd.} \end{cases}$$

For a general homogeneous Riemannian manifold X we calculate the leading three terms in the magnitude as the manifold is scaled up: the first term is proportional to the volume, the second term vanishes and the third term is proportional to the total scalar curvature (tsc). Writing tX for X scaled up by a factor of $t > 0$ and writing ω_n for the volume of the unit n-ball, we have

$$|tX| = \tfrac{1}{n!\,\omega_n}\,\mathrm{vol}(X)t^n + 0\cdot t^{n-1} + \tfrac{n+1}{6\,n!\,\omega_n}\,\mathrm{tsc}(X)t^{n-2} + O(t^{n-3}) \quad \text{as } t\to\infty.$$

This suffices to determine the asymptotics of the magnitude of a homogeneous surface, this asymptotic expression involving just the area and Euler characteristic of the surface Σ:

$$|t\Sigma| = \tfrac{1}{2\pi}\,\mathrm{area}(\Sigma)t^2 + \chi(\Sigma) + O(t^{-2}) \qquad \text{as } t\to\infty.$$

This expression in the area and Euler characteristic is precisely the penguin valuation of [11].

There are a few things to note. The first thing to note is that although we use the measure theoretic approach rather than the finite approximation approach, we show that all the results of [6] obtained using the finite approximations are all also obtained using the measure theoretic approach.

The second thing to note is that in the cases that are known, namely the n-spheres and surfaces, the constant term is precisely the Euler characteristic. This is particularly interesting as the magnitude arose from a category theoretic generalization of the notion of Euler characteristic of various mathematical objects. Indeed we might have named magnitude as "the Euler chacteristic of metric spaces" if that weren't such a potentially confusing term.

The final thing to note is that the intrinsic volumes, which are the terms so far identified in the asymptotic expansion all appear in the asymptotic expansion of the heat kernel [1] and, as the definition of is slightly reminiscent of the heat kernel, this looks intriguing.

Before giving a more detailed synopsis of the contents of the paper, it is worth making some comments about the metric that we are considering on a Riemannian manifold. There is potential for confusion here in that we are considering metric spaces and Riemannian metrics, so the word 'metric' is being used with two different senses. To reduce the likelihood of confusion, in this paragraph and the next paragraph we will talk about 'distance metric' for the metric on a metric space and 'Riemannian metric' for an inner product on each tangent space of a smooth manifold: a distance metric is a global object, a Riemannian metric is an infinitessimal object. In order to define the magnitude of a Riemannian manifold we need a distance metric on the manifold, we will be considering the intrinsic distance metric which arises in the following way. A Riemannian metric gives rise to an arc-length function and this gives rise to a distance metric by defining the distance between two points to be the infimum of the lengths of the paths between the two points.

If there is a Riemannian embedding of a Riemannian manifold in Euclidean space then there are two obvious distance metrics, the intrinsic metric and the subspace metric: in this paper we are primarily considering the intrinsic metric whereas in [6] and [11] we considered mainly the subspace metric. So, for instance, on the Earth, the intrinsic distance metric is realized by travelling over the surface of the Earth, but the subspace distance metric is realized by tunnelling *through* the Earth. We compare the asymptotics for the magnitude of the n-sphere with the subspace metric and to that with the intrinsic metric; they are seen to have the same leading term but different lower order terms.

There now follows a more detailed synopsis of what is in this paper.

Synopsis

In Section 1 we define the magnitude of a metric space using a measure on the space. The key observation here is that if X is a homogeneous metric space and μ is a non-zero homogeneous measure on X, then the magnitude of X is given by the following formula: for any $y \in X$,

$$|X| = \frac{\int_{x\in X} \mathrm{d}\mu}{\int_{x\in X} e^{-d(x,y)}\mathrm{d}\mu},$$

provided that the denominator is finite and non-zero. It is also shown in this section that the measure theoretic definition gives the same magnitude as the finite subset approach did for the circle, line segment and Cantor set in [6].

In Section 2 we give a brief exposition on the notion of intrinsic volumes of Riemannian manifolds. Intrinsic volumes are defined for a wide class of subsets of Euclidean space and include such invariants as the volume, the surface area of the boundary and the Euler characteristic. In [6] and [11] we mainly considered these for polyconvex sets — that is unions of convex sets — following Klain and Rota's treatment [3], but here we consider a differential treatment, utilizing [8] and [2]. One key point for us is that for M^n a closed submanifold of $\mathbb{R}^k$ these intrinsic volumes are intrinsic in the sense of differential geometry — that is to say they are independent of the embedding and depend only on the Riemannian metric of M^n. So for such a Riemannian manifold there are $n+1$ intrinsic volumes $\{\mu_i\}_{i=0}^n$, but it turns out that about half of these vanish because M^n is closed, $\mu_i(M^n) = 0$ if $n-i$ is odd: the fact that $\mu_{n-1}(M^n) = 0$ can be explained by the fact that μ_{n-1} measures the surface of the boundary, which is of course trivial when M^n is closed. The non-zero intrinsic volumes are also known in this case as Killing-Lipschitz curvatures and in a few cases are well-known invariants: $\mu_n(M^n)$ is the volume of M^n; the next non-trivial intrinsic volume $\mu_{n-2}(M^n)$ is the total scalar curvature (tsc) of M^n; and $\mu_0(M^n)$ is the Euler characteristic of M^n. In general these can be obtained by integrating over M^n a certain form defined in terms of the curvature.

In Section 3 we get to one of the main results which is an explicit formula for $\left|S_R^n\right|$ the magnitude of the n-sphere of radius R equipped with its intrinsic metric. (Here it is slightly misleading to talk of the radius of the n-sphere as it is being thought of as an abstract manifold with the arclength distance metric and not as a subset of $\mathbb{R}^{n+1}$ with the subspace distance metric; however it is perhaps slightly less comfortable to talk of the sphere of curvature R^{-2}.) The formula has many of the properties you might expect, such as $|S_R^n| \to 1$ as $R \to 0$. Asymptotically as $R \to \infty$, writing ω_n for the volume of the unit n-ball, we get

$$\begin{aligned}|S_R^n| = \tfrac{1}{n!\,\omega_n}\operatorname{vol}(S_1^n)R^n + 0\cdot R^{n-1} + \tfrac{n+1}{6\,n!\,\omega_n}\operatorname{tsc}(S_1^n)R^{n-2} + 0\cdot R^{n-3}\\ + \cdots + \chi(S_1^n) + O(e^{-R}).\end{aligned}$$

This is certainly consistent with the asymptotics being described by the intrinsic volumes: for instance the alternate terms vanish and we pick up the volume, the total scalar curvature and the Euler characteristic.

In Section 4 we see the other main result that for all homogeneous Riemannian manifolds the first three terms in the asymptotic expansion are like those in the above expansion, further work will be needed to get more terms in the expansion. However, this is sufficient to show that for a homogeneous Riemannian surface asymptotically the magnitude has the form conjectured for the asymptotic magnitude of metric subsets of Euclidean space in [6] and [11].

In Section 5 the magnitude of the n-sphere with its subspace metric is considered. A closed form is given for $n = 2$, but not for general n; however, for general n it is shown that the leading term in the asymptotic expansion is the same as for the intrinsic metric, namely $\operatorname{vol}(S_R^n)/n!\,\omega_n$, but that the next non-trivial term is different.

Acknowlegements

It is a pleasure to thank Jonathan Jordan, Tom Leinster and David Speyer for their contributions to Section 1, as well as for other informative discussions. I would also like to thank Mark Meckes for comments on an earlier draft.

1 Extending magnitude to infinite metric spaces

In this section we first recall the definition of the magnitude of finite metric spaces in terms of weights and generalize it to infinite metric spaces using weight measures. We show that Speyer's theorem for homogeneous spaces immediately generalizes and that this definition is consistent with previous calculations for intervals, circles and Cantor sets.

1.1 Generalizing magnitude using measures

Leinster introduced the notion of the Euler characteristic of a finite category which is not always defined, but which generalizes many pre-existing notions of Euler characteristic, such as the Euler characteristic of a group or a poset or the cardinality of a set. Then using Lawvere's observation that a metric space can be viewed as an enriched category he defined the notion of the Euler characteristic or cardinality of a finite metric space — it was decided that these terms were already too overburdened, so we renamed the concept the 'magnitude' of a metric space. This has the following definition.

Definition. For X a finite metric space, a *weighting* on X is an assignment of a number $w_x \in \mathbb{R}$ to each point $x \in X$ such that the *weight equation* is satisfied for each point $y \in X$:

$$\sum_{x \in X} e^{-d(x,y)} w_x = 1.$$

If a weighting exists for X then the magnitude $|X|$ is defined to be the sum of the weights:

$$|X| := \sum_x w_x.$$

Note the following two things about the definition. Firstly, the weights can be negative. Secondly, if more than one weighting exists then the magnitude is independent of the choice of weighting (a proof appears below in the more general measure theoretic setting).

If you require a little intuition then one way of thinking about the weight equations is as follows. Each point can be thought of as an organism, with the weight being the amount of 'heat' being generated by that point (a negative weight denoting some sort of refrigeration). Each organism experiences the heat generated by the other organisms in a fashion which decays exponentially with the distance. The organisms each wish to experience unit heat and this is what is expressed by the weight equation.

We can try to extend the idea of magnitude to non-finite metric spaces. Two approaches present themselves.

- Use finite approximation to the metric space.

- Use a measure in the definition of a weighting.

The first of these approaches was explored in [6] and [11]. In this approach a metric space X is approximated by taking a sequence $\{X^{(i)}\}_{i=1}^{\infty}$ of finite subsets of X, which converges to X in the Hausdorff topology, so $X^{(i)} \to X$ as $i \to \infty$. One can then take the corresponding sequence of magnitudes $\{|X^{(i)}|\}_{i=1}^{\infty}$ and hope that they tend to a limit, and furthermore hope that the limit is independent of the choice of approximating sequence. This seems to work in many cases such as compact subsets of Euclidean space. This approach has the advantage that it can be implemented on a computer to obtain approximations to the magnitude of some spaces as in [11].

The second approach is the one that will be used in this paper. This was independently suggested to me by Tom Leinster and David Speyer (my own thoughts on the matter lay more in realm of currents and differential forms). The idea is to generalize the definition of magnitude using measures in the following way.

Definition. If X is a metric space then a *weight measure* on X is a signed measure ν on X such that for all $y \in X$

$$\int_{x\in X} e^{-d(x,y)}\mathrm{d}\nu(x) = 1.$$

If a weight measure ν exists then $|X|$, the *magnitude* of X, is defined to be the mass of X with respect to ν:

$$|X| := \int_X \mathrm{d}\nu.$$

Note that the magnitude, if it exists, is independent of the choice of weight measure. Suppose that ν and $\overline{\nu}$ are weight measures then

$$\begin{aligned}\int_{x\in X}\mathrm{d}\nu(x) &= \int_{x\in X}\left(\int_{x'\in X} e^{-d(x',x)}\mathrm{d}\overline{\nu}(x')\right)\mathrm{d}\nu(x)\\ &= \int_{x'\in X}\left(\int_{x\in X} e^{-d(x,x')}\mathrm{d}\nu(x)\right)\mathrm{d}\overline{\nu}(x') = \int_{x'\in X}\mathrm{d}\overline{\nu}(x').\end{aligned}$$

It is worth giving a brief mention here to some connections between measure theory and Riemannian geometry (for more details see, for example, [8]). If M^n is an orientable Riemannian manifold then there is a volume form dvol, well-defined up to sign — the choice of sign corresponding to the choice of orientation. The volume form is defined by smoothly picking an ordered orthonormal basis $\partial/\partial x_1, \dots, \partial/\partial x_n$ for each tangent space, taking the dual basis $\mathrm{d}x_1, \dots, \mathrm{d}x_n$ and defining $\mathrm{dvol} := \mathrm{d}x_1 \wedge \cdots \wedge \mathrm{d}x_n$. Integrating with respect to this volume form does not quite give a measure because of the sign ambiguity — think how on the real line we have $\int_a^b f\,\mathrm{d}x = -\int_b^a f\,\mathrm{d}x$. However, there is an associated measure $|\mathrm{vol}|$, called the density, which obviates the sign problem. In the case of Euclidean space this density is the usual Lebesgue measure. As no confusion should occur, we will not distinguish between the volume form and the associated density.

If M^n is an orientable n-dimensional submanifold of Euclidean space $\mathbb{R}^k$ then there are two obvious measures that one might consider. Firstly the Riemannian metric on $\mathbb{R}^k$ can be pulled back to M^n to make it into an orientable

Riemannian manifold so we can use the associated density. Alternatively, one could use the n-dimensional Hausdorff measure on $\mathbb{R}^k$ restricted to M^n. Provided that the Hausdorff measure is normalized so that the n-dimensional cube $[0,1]^n$ has unit measure, these two measures on M^n coincide.

One of the key tools of this paper is the following generalization of Speyer's theorem on the magnitude of finite homogeneous spaces given in [6]. Recall that a homogeneous space is one for which there is a transitive group of isometries, or, in other words, one in which all of the points look the same.

Theorem 1 (Speyer's Homogeneous Magnitude Theorem)**.** *Suppose that X is a homogeneous metric space and μ is an invariant metric on X then $\int_{x\in X} e^{-d(x,y)}\mathrm{d}\mu$ is independent of y. If this quantity is non-zero and finite then a weight measure on X is given by*

$$\frac{\mu}{\int_{x\in X} e^{-d(x,y)}\mathrm{d}\mu}.$$

Thus the magnitude is given by

$$|X| = \frac{\int_{x\in X}\mathrm{d}\mu}{\int_{x\in X} e^{-d(x,y)}\mathrm{d}\mu}.$$

Proof. This follows immediately from the definition of magnitude. □

It is worth pointing out here that every *compact* homogeneous space has a unique-up-to-scaling, invariant, positive measure, thus has a well-defined magnitude.

Aside from the calculations for the interval and Cantor set given below, this theorem is the only way I currently know for calculating the magnitude of non-finite metric spaces.

1.2 Agreement with previous calculations

We can now look at the spaces whose cardinality was defined using finite approximations in [6], and show that the same results are obtained using weight measures. These spaces are closed straight line segments, circles and Cantor sets.

We consider first L_ℓ the length ℓ closed line segment. The following was essentially told to me by Tom Leinster and David Speyer independently.

Theorem 2. *Let μ be the Lebesgue measure on L_ℓ the length ℓ line segment and let δ_a and δ_b be the Dirac delta measures supported at the two respective end points. Then a weight measure on L_ℓ is given by $\frac{1}{2}(\delta_a+\delta_b+\mu)$. Hence the magnitude is simply:*

$$|L_\ell| = 1 + \ell/2.$$

Proof. It is just necessary to show that the given measure satisfies the weight equation for every point $y \in L_\ell$. We can consider L_ℓ as the subset $[a,b] \subset \mathbb{R}$ where $b-a=\ell$, then for every $y \in L_\ell$

$$\begin{aligned}&\int_{x\in L_\ell} e^{-d(x,y)}\tfrac{1}{2}\left(\mathrm{d}\delta_a+\mathrm{d}\delta_b+\mathrm{d}\mu\right)\\ &\qquad\qquad = \tfrac{1}{2}\left(e^{-d(a,y)}+e^{-d(b,y)}+\int_a^y e^{-(y-x)}\mathrm{d}x+\int_y^b e^{-(x-y)}\mathrm{d}x\right)\end{aligned}$$

$$= \tfrac{1}{2}\left(e^{a-y} + e^{y-b} + [e^{x-y}]_a^y - [e^{y-x}]_y^b\right) = 1.$$

Thus the magnitude is given by

$$|L_\ell| = \int_{L_\ell} \tfrac{1}{2}\big(\mathrm{d}\delta_a + \mathrm{d}\delta_b + \mathrm{d}\mu\big) = \tfrac{1}{2}(1 + 1 + \ell) = 1 + \ell/2,$$

as required. $\square$

Now turn to the ternary Cantor set. The following lemma, pointed out to me by Jonathan Jordan, will be rather useful in calculating the magnitude. It says that if we have a weight measure on a subset of the line which on some subinterval is a multiple of the Lebesgue measure then if the subinterval is removed then a weight measure is obtained for the resulting space by putting simple Dirac delta measures at the end points of the removed subinterval.

Lemma 3. *If X is a subset of $\mathbb{R}$ with ν a weight measure on X with $[a,b] \subset X$ and $\nu|_{[a,b]} = \frac{1}{2}\mu|_{[a,b]}$, then a weight measure on $X \setminus (a,b)$ is given by*

$$\nu|_{X\setminus(a,b)} + \tfrac{1}{2}\tanh\big(\tfrac{b-a}{2}\big)(\delta_a + \delta_b).$$

So the magnitude satisfies

$$|X \setminus (a,b)| = |X| - \tfrac{b-a}{2} + \tanh\big(\tfrac{b-a}{2}\big).$$

Proof. We need the easy-to-verify identity $\frac{e^A - e^B}{e^A + e^B} = \tanh\big(\frac{A-B}{2}\big)$ to obtain $e^{y-a} - e^{y-b} = \tanh\big(\frac{b-a}{2}\big)\big(e^{y-a} + e^{y-b}\big)$. Thus for $y \le a$

$$\begin{aligned}
\int_{x\in X\setminus(a,b)} & e^{-d(x,y)}\big[\mathrm{d}\nu + \tfrac{1}{2}\tanh\big(\tfrac{b-a}{2}\big)(\mathrm{d}\delta_a + \mathrm{d}\delta_b)\big] \\
&= \int_{x\in X} e^{-d(x,y)}\mathrm{d}\nu - \int_{x\in[a,b]} e^{-d(x,y)}\tfrac{1}{2}\mathrm{d}\mu \\
&\qquad + \tfrac{1}{2}\tanh\big(\tfrac{b-a}{2}\big)\int_{x\in X\setminus(a,b)} e^{-d(x,y)}(\mathrm{d}\delta_a + \mathrm{d}\delta_b) \\
&= 1 + \tfrac{1}{2}[e^{y-b} - e^{y-a}] + \tfrac{1}{2}\tanh\big(\tfrac{b-a}{2}\big)\big(e^{y-a} + e^{y-b}\big) \\
&= 1.
\end{aligned}$$

The expression for the weight follows immediately. $\square$

This can now be repeatedly to obtain the magnitude of the Cantor set, and this agrees with the answer in [6]. Note that there the Cantor set was approximated below via finite subsets, and here it is approximated above by subsets of $[0,\ell]$ with non-zero measure.

Theorem 4. *The length ℓ ternary Cantor set T_ℓ has magnitude given by*

$$|T_\ell| = 1 + \sum_{i=1}^{\infty} 2^{i-1}\tanh\left(\frac{\ell}{2.3^i}\right).$$

Proof. Start by defining $T_{\ell,0}$ to be a length ℓ line interval which is parametrize by the interval $[0,1]$ with the points in the unit interval being identified with their ternary exansion, so that a point a third of the way along $T_{\ell,0}$ has expansion 0.1. The interval $T_{\ell,0}$ is given the standard weight measure as in Theorem 2, $\frac{1}{2}(\mu + \delta_0 + \delta_1)$, which will be called $\nu_{\ell,0}$. Define $T_{\ell,i}$ and its weight measure $\nu_{\ell,i}$ inductively by first removing from $T_{\ell,i-1}$ the open middle third of each maximal subinterval; this means removing points having expansions e of the form

$$0.a_1a_2\cdots a_{i-1}1 < e < 0.a_1a_2\cdots a_{i-1}2 \quad \text{where } a_1,\ldots,a_{i-1} \in \{0,2\}.$$

The length of each removed open interval will be $(1/3)^i\ell$. By Lemma 3 above we obtain a weight measure $\nu_{\ell,i}$ by restricting the weight measure $\nu_{\ell,i-1}$ on $T_{\ell,i-1}$, except on the newly pruned end points where we have to put a Dirac delta measure of mass $\frac{1}{2}\tanh((1/3)^i\ell/2)$.

Taking the limit, we obtain we obtain a measure ν on the ternary Cantor set T_ℓ, this measure is the restriction of half the Lebesgue measure plus a Dirac delta on each point in the Cantor set which has a finite ternary expansion — the mass at a point with i terms in the ternary expansion is $\frac{1}{2}\tanh((1/3)^i\ell/2)$, and there are 2^i such points, so the total mass of ν, i.e., the magnitude is precisely

$$T_\ell = 1 + \sum_{i=1}^{\infty} 2^i \frac{1}{2} \tanh\left(\frac{\ell}{2.3^i}\right),$$

as required. □

Now finish this section by considering the circle.

Theorem 5. *The cardinality of C_ℓ the circle of circumference ℓ is given by*

$$|C_\ell| = \frac{\ell}{\int_0^{2\pi} e^{-d(x,y)}\mathrm{d}x}.$$

Proof. This follows immediately from the homogeneity theorem. □

In conclusion, the confidence expressed in [6] when defining the magnitude in terms of subsets is now justified. In [6] it was unclear that the answers given for the Cantor set and circle were independent of the choice of approximating subsets; but they agree with the answers given here which are independent of the choice of weight measure.

2 Intrinsic volumes for Riemannian manifolds

This section is a brief exposition on intrinsic volumes for Riemannian manifolds; these invariants are also known as curvature measures, Lipshitz-Killing curvatures, generalized curvatures and quermassintegrale. I will mention Weyl's Tube Formula and the connection with total scalar curvature and volumes of geodesic speres. This treatment is mainly obtained from the books [2] and [8]. This section also serves to fix some notation and conventions.

In [6], following [3], we considered the intrinsic volumes $\{\mu_i\}_{i=1}^N$ as functions on polyconvex subsets of Euclidean space $\mathbb{R}^N$. In fact the intrinsic volumes are defined for a much larger class of subsets of $\mathbb{R}^N$ via the theory of curvature measures (see [8]). The intrinsic volumes can be defined for subsets which have an appropriate notion of unit normal bundle — a so-called normal cycle. This class of subsets includes smooth submanifold with boundary and more generally sets of positive reach. In general, the basic properties of the intrinsic volumes are the following.

Additivity $\mu_i(X_1 \cup X_2) = \mu_i(X_1) + \mu_i(X_2) - \mu_i(X_1 \cap X_2)$.

Homogeneity $\mu_i(tX) = t^i \mu_i(X)$.

Normalization $\mu_i([0,1]^i) = 1$.

Then $\mu_N(X)$ is the usual N-dimensional volume of X and $\mu_0(X)$ is the Euler characteristic of X.

For a closed smooth submanifold of $\mathbb{R}^N$ there are many formulas for the intrinsic volumes. The simplest formulas are for when the submanifold in question is a hypersurface $H^n \subset \mathbb{R}^{n+1}$. In this case, at each point in H there are n principal curvatures $\kappa_1, \ldots, \kappa_n$, and the jth symmetrized curvatures s_j is defined to be the jth-elementary symmetric function in the principal curvatures: $\prod_l (1 + t\kappa_l) = \sum_j s_j t^j$. The intrinsic volumes are given, up to factor, by integrating these symmetrized curvatures over the submanifold. More precisely, recalling that σ_j denotes the volume of the unit j-sphere, for $0 \leq i \leq n$,

$$\mu_i(H^n) = \begin{cases} \dfrac{2}{\sigma_{n-i}} \displaystyle\int_H s_{n-i} \,\mathrm{dvol} & \text{if } n-i \text{ is even,} \\ 0 & \text{if } n-i \text{ is odd.} \end{cases}$$

From this one obtains, for instance, $\mu_n(H^n) = \mathrm{vol}(H^n)$. This allows us to calculate the intrinsic volumes of $\overline{S}^n_R \subset \mathbb{R}^{n+1}$ the n-sphere of radius R sitting in $\mathbb{R}^{n+1}$ in the usual way. Here all of the principal curvatures are the reciprocal of the radius, R^{-1}, so the symmetrized curvatures are given by $s_j = \binom{n}{j} R^{-j}$ and so, for $0 \leq i \leq n$,

$$\mu_i(\overline{S}^n_R) := \begin{cases} \dfrac{2\sigma_n}{\sigma_{n-i}} \dbinom{n}{i} R^i & \text{if } n-i \text{ is even,} \\ 0 & \text{if } n-i \text{ is odd.} \end{cases}$$

In the case of a submanifold of codimension greater than 1 there are not principal curvatures, but the intrinsic volumes can be expressed in terms of the marginally more complicated Lipschitz-Killing curvatures. However it is still true that for X^n a closed submanifold $\mu_i(X^n) = 0$ whenever $n - i$ is odd. From these curvature expressions, as Weyl notes, a good undergraduate could derive the following Tube Formula. As an easy exercise, you may wish to verify this for the n-sphere using the formulas given above for the intrinsic volumes.

Theorem 6 (Weyl's Tube Formula). *Suppose that $X^n \subset \mathbb{R}^N$ is a closed, smooth submanifold of Euclidean space, that $B_\epsilon X \subset \mathbb{R}^N$ is the set of points of distance at* *most ϵ from X, and that ω_i is the volume of the unit i-ball, then*

$$\mathrm{vol}_N(B_\epsilon X) = \sum_{i=0}^{N} \mu_{N-i}(X)\omega_i \epsilon^i.$$

Weyl's key observation, however, was that the intrinsic volumes of X can be expressed purely in terms of its *intrinsic* geometry — we have already observed that $\mu_n(X^n) = \mathrm{vol}_n(X)$ and $\mu_0(X^n) = \chi(X^n)$. So the intrinsic volumes only depend on the Riemannian metric of X and not on the way it is embedded, nor on the codimension in which it is embedded. For instance, the intrinsic volumes can be written as polynomial Riemann curvature tensor. However, in this paper there is just one of these intrinsic volumes that we are interested in. After the n-volume, the next non-trivial intrinsic volume is proportional to the *total scalar curvature*:

$$\mu_{n-2}(X^n) = \frac{1}{4\pi} \int_{x \in X} \tau(x)\, \mathrm{dvol}.$$

Here $\tau(x)$ is the *scalar curvature* which can be thought of as measuring the "lack of stuff" near x. For instance, if you draw a circle on the surface of the Earth then it has a circumference than a Euclidean circle with the same radius — this deficiency in the circumference is measured by the scalar curvature (in the case of a surface the scalar curvature is twice the Gaussian curvature). To make this precise, for $x \in X$ and $r > 0$, let $F_r(x) \subset X$ be the set of points at a distance of r from x; for r sufficiently small this will be an $(n-1)$-sphere, known as a *geodesic sphere*. The scalar curvature $\tau(x)$ at x is uniquely determined by the second order term in the power series expansion of the volume of geodesic spheres centered at x, in the following sense:

$$\mathrm{vol}_{n-1}\big(F_r(x)\big) = \sigma_{n-1} r^{n-1} \left(1 - \frac{\tau(x)}{6n} r^2 + O(r^4)\right) \qquad \text{as } r \to 0.$$

It is in this way that the scalar curvature can be viewed as a measure of the "lack of stuff" near x. The above formula will be used later in the calculation of sub-leading term in the asymptotics of the magnitude of homogeneous metric spaces. As an example, note that in an n-sphere of radius R we have, for all x, $\mathrm{vol}_{n-1}\big(F_r(x)\big) = \sigma_{n-1}\left(R\sin(r/R)\right)^{n-1}$. So the scalar curvature is given by $\tau = n(n-1)R^{-2}$ which you can check is consistent with the value calculated for $\mu_{n-2}(S^n_R)$ above.

3 Calculation of the magnitude of an n-sphere

This section consists of one of the main results of this paper which is an explicit formula for the magnitude of the n-sphere. The asymptotic behaviour is also considered and the Euler characteristic is seen to be the constant term in the asymptotic expansion.

We take S^n_R the n-sphere with the standard metric of curvature $1/R^2$ (which means that it isometrically embeds in $\mathbb{R}^{n+1}$ with radius R) thought of as a homogeneous space. From Speyer's Homogeneous Magnitude Theorem (Theo-

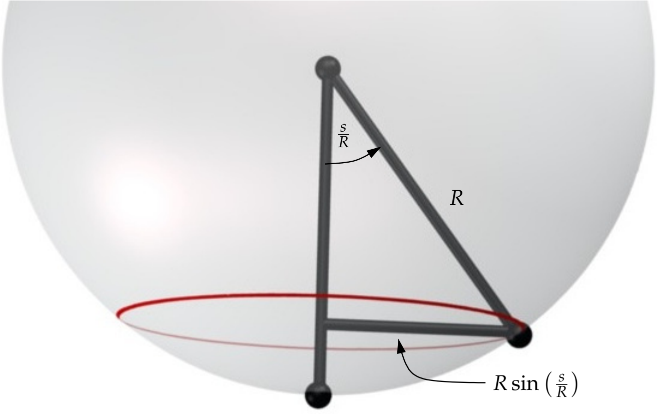

Figure 1: The Euclidean radius of the points F_s at a distance s from x_0 is $R\sin\left(\frac{s}{R}\right)$.

rem 1) the magnitude is given by

$$|S^n_R| = \frac{\int_{x\in S^n_R}\mathrm{dvol}}{\int_{x\in S^n_R} e^{-d(x_0,x)}\mathrm{dvol}} \qquad \text{for any } x_0 \in S^n_R.$$

This can be calculated explicitly.

Theorem 7. *For $n \geq 1$, the magnitude of the homogeneous n-sphere of radius R is given by*

$$|S^n_R| = \begin{cases} \dfrac{2\Big(\big(\frac{R}{n-1}\big)^2+1\Big)\Big(\big(\frac{R}{n-3}\big)^2+1\Big)\dots\Big(\big(\frac{R}{1}\big)^2+1\Big)}{1+e^{-\pi R}} & \textit{for n even} \\[2ex] \dfrac{\pi R\Big(\big(\frac{R}{n-1}\big)^2+1\Big))\Big(\big(\frac{R}{n-3}\big)^2+1\Big)\dots\Big(\big(\frac{R}{2}\big)^2+1\Big)}{1-e^{-\pi R}} & \textit{for n odd,} \end{cases}$$

where for $n = 1$ the numerator is interpreted as being πR.

Proof. The idea is to find some explicit integrals to calculate magnitude, evaluate them to obtain $|S^1_R|$ and $|S^2_R|$, show that the induction formula holds,

$$|S^{n+2}_R| = \Big(\big(\tfrac{R}{n+1}\big)^2+1\Big)|S^n_R|,$$

and then apply induction.

We first fix some point x_0 and define the coordinate s on the n-sphere to be the distance from the point x_0, so $s(x) := d(x, x_0)$. The points at a distance s from x_0 form an $(n-1)$-sphere F_s of Euclidean radius $R\sin(\frac{s}{R})$, see Figure 1; thus, writing σ_{n-1} for the volume of the unit $(n-1)$-sphere, the volume of F_s is given by $\sigma_{n-1}\big(R\sin(\frac{s}{R})\big)^{n-1}$. Locally, as s parametrizes distance, the volume form on S^n_R is the product of $\mathrm{d}s$ and the volume form on F_s. So

$$|S^n_R| := \frac{\int_{x\in S^n_R}\mathrm{dvol}}{\int_{x\in S^n_R} e^{-d(x_0,x)}\mathrm{dvol}} = \frac{\int_{s=0}^{\pi R}\int_{F_s}\mathrm{dvol}_{F_s}\,\mathrm{d}s}{\int_{s=0}^{\pi R}\int_{F_s} e^{-s}\,\mathrm{dvol}_{F_s}\,\mathrm{d}s}$$

$$\begin{aligned}
&= \frac{\int_{s=0}^{\pi R} \sigma_{n-1}\big(R\sin(\tfrac{s}{R})\big)^{n-1}\,\mathrm{d}s}{\int_{s=0}^{\pi R} e^{-s}\sigma_{n-1}\big(R\sin(\tfrac{s}{R})\big)^{n-1}\,\mathrm{d}s} \\
&= \frac{\int_{r=0}^{\pi} \sin^{n-1}(r)\,\mathrm{d}r}{\int_{r=0}^{\pi} e^{-rR}\sin^{n-1}(r)\,\mathrm{d}r},
\end{aligned}$$

where we made the substitution $s = rR$. This can be evaluated for the 1-sphere and 2-sphere:

$$\begin{aligned}
\left|S_R^1\right| &= \frac{\int_0^{\pi}\mathrm{d}r}{\int_0^{\pi} e^{-rR}\,\mathrm{d}r} = \frac{\pi}{-\frac{1}{R}[e^{-rR}]_0^{\pi}} = \frac{\pi R}{1-e^{-\pi R}}\ ; \\
\left|S_R^2\right| &= \frac{\int_0^{\pi}\sin(r)\,\mathrm{d}r}{\int_0^{\pi} e^{-rR}\sin(r)\,\mathrm{d}r} = \frac{2}{\operatorname{Im}\int_0^{\pi} e^{-rR}e^{ir}\,\mathrm{d}r} = \frac{2(R^2+1)}{1+e^{-\pi R}}\ .
\end{aligned}$$

These will form the base cases for the induction. For the inductive step, write

$$K_n := \int_0^{\pi} \sin^{n-1}(r)\,\mathrm{d}r \quad \text{and} \quad I_n := \int_0^{\pi} e^{-rR}\sin^{n-1}(r)\,\mathrm{d}r$$

so that $\left|S_R^n\right| = \frac{K_n}{I_n}$. We will show that

$$(n+1)K_{n+2} = nK_n \quad \text{and} \quad (n+1)\Big(\big(\tfrac{R}{n+1}\big)^2+1\Big)I_{n+2} = nI_n$$

from which it is immediate that $|S_R^{n+2}| = \Big(\big(\tfrac{R}{n+1}\big)^2+1\Big)|S_R^n|$, and the required result follows by induction.

To prove the relation for K_n we observe

$$\begin{aligned}
K_{n+2} &= \int_0^{\pi}\sin^{n+1}(r)\,\mathrm{d}r = \int_0^{\pi}\Big(1-\cos^2(r)\Big)\sin^{n-1}(r)\,\mathrm{d}r \\
&= \int_0^{\pi}\sin^{n-1}(r)\,\mathrm{d}r - \int_0^{\pi}\cos(r)\,\Big(\cos(r)\sin^{n-1}(r)\Big)\,\mathrm{d}r \\
&= \int_0^{\pi}\sin^{n-1}(r)\,\mathrm{d}r - \Big[\cos(r)\tfrac{1}{n}\sin^n(r)\Big]_0^{\pi} + \int_0^{\pi}(-\sin(r))\,\Big(\tfrac{1}{n}\sin^n(r)\Big)\,\mathrm{d}r \\
&= K_n - 0 - \tfrac{1}{n}K_{n+2},
\end{aligned}$$

from which we deduce $(n+1)K_{n+2} = nK_n$, as we wanted.

To prove the relation for I_n we perform integration by parts twice:

$$\begin{aligned}
I_{n+2} &= \int_0^{\pi} e^{-rR}\sin^{n+1}(r)\,\mathrm{d}r \\
&= \Big[-\tfrac{1}{R}e^{-rR}\sin^{n+1}(r)\Big]_0^{\pi} - \int_0^{\pi} -\tfrac{1}{R}e^{-rR}(n+1)\cos(r)\sin^n(r)\,\mathrm{d}r \\
&= 0 + \tfrac{(n+1)}{R}\Big[-\tfrac{1}{R}e^{-rR}\cos(r)\sin^n(r)\Big]_0^{\pi} \\
&\qquad - \tfrac{(n+1)}{R}\int_0^{\pi} -\tfrac{1}{R}e^{-rR}\Big(-\sin(r)\sin^n(r) + n\cos(r)\cos(r)\sin^{n-1}(r)\Big)\,\mathrm{d}r \\
&= 0 + 0 + \tfrac{(n+1)}{R^2}\int_0^{\pi} e^{-rR}\Big(-\sin^{n+1}(r) + n\Big(1-\sin^2(r)\Big)\sin^{n-1}(r)\Big)\,\mathrm{d}r \\
&= -\tfrac{(n+1)^2}{R^2}I_{n+2} + \tfrac{(n+1)n}{R^2}I_n.
\end{aligned}$$

From this we deduce that $(n+1)\big((\frac{R}{n+1})^2+1\big)I_{n+2} = nI_n$ which suffices to complete the inductive step and hence we complete the proof. $\square$

The first thing to note from this is that the formula for $|S^n_R|$ in the above theorem also works for S^0_R provided that this notation is interpreted correctly. If S^0_R is taken to mean the two points on the equator of S^1_R the radius R circle, then S^0_R is the metric space consisting of two points a distance πR apart, and then it is immediate that the magnitude is given by

$$|S^0_R| = \frac{2}{1+e^{-\pi R}}.$$

The next thing to note is the $|S^n_R| \to 1$ as $R \to 0$, so effectively, the n-sphere looks more and more like a point as it gets smaller and smaller.

A third thing to note is that the two formulae can be combined into a single formula which clearly demonstrates the roots of the numerator lying at alternate integral points on the imaginary axis:

$$|S^n_R| = \alpha_n \frac{(R-(n-1)i)\,(R-(n-3)i)\ldots\big(R-(-n+3)i\big)\big(R-(-n+1)i\big)}{1+e^{-\pi(R+ni)}}$$

where $i=\sqrt{-1}$ and α_n is a constant which ensures that $|S^n_R| \to 1$ as $R \to 0$. The roots of the numerator are also roots of the denominator, but I have no idea of the relevance of this.

A fourth things worthy of note is that the denominators very quickly converge to 1. This means that the behaviour for R away from zero, say for $R > 4$, is dominated by the numerator. We can define $P(S^n_R)$, for $n \geqslant 0$, to be the numerator:

$$P(S^n_R) := \begin{cases} 2\Big(\big(\frac{R}{n-1}\big)^2+1\Big)\Big(\big(\frac{R}{n-3}\big)^2+1\Big)\ldots\Big(\big(\frac{R}{1}\big)^2+1\Big) & \text{for } n \text{ even,} \\ \pi R\Big(\big(\frac{R}{n-1}\big)^2+1\Big)\Big(\big(\frac{R}{n-3}\big)^2+1\Big)\ldots\Big(\big(\frac{R}{2}\big)^2+1\Big) & \text{for } n \text{ odd,} \end{cases}$$

where the empty product is interpreted as 1 for $n=0$ and $n=1$. This polynomial in R gives us the asymptotic behaviour of $|S^n_R|$ in the sense that $|S^n_R| - P(S^n_R) \to 0$ as $R \to \infty$. Previously for the closure of an open subset of Euclidean space the asymptotics of the magnitude were conjectured to be controlled by certain intrinsic volumes. In the case of the spheres the leading term and constant term can be seen to behave in the same way.

Theorem 8. *The leading term of $P(S^n_R)$ is proportional to the volume of the n-sphere S^n_R and the constant term is equal to its Euler characteristic: writing ω_n for the volume of the unit n-ball,*

$$P(S^n_R) = \frac{\mathrm{vol}(S^n_1)R^n}{n!\,\omega_n} + \cdots + \chi(S^n_1).$$

Proof. To deal with the Euler characteristic first, note that the Euler characteristic of a sphere just depends on the parity of the dimension: $\chi(S^{2i}) = 2$ and $\chi(S^{2i+1}) = 0$. The constant term in the polynomial $P(S^n_R)$ is immediately seen to have exactly this property.

That the leading term has the required form can be proved inductively using the inductive formula

$$P(S_R^n) = \left(\tfrac{R}{n-1}\right)^2 P(S_R^{n-2})$$

together with the following relations (see, for example, [3]) for ω_n the volume of the unit n-ball and σ_n the volume of the unit n-sphere:

$$\omega_n = \tfrac{2\pi}{n}\omega_{n-2} \quad \text{and} \quad \sigma_n = \tfrac{2\pi}{n-1}\sigma_{n-2}.$$

Assuming that the result is true for $P(S_R^{n-2})$ and writing Top for the top coefficient of a polynomial, we have

$$\begin{aligned}
\operatorname{Top}\Big(P(S_R^n)\Big) &= \operatorname{Top}\Big(\left(\tfrac{R}{n-1}\right)^2 P(S_R^{n-2})\Big) = \operatorname{Top}\Big(\left(\tfrac{R}{n-1}\right)^2\Big)\operatorname{Top}\Big(P(S_R^{n-2})\Big)\\
&= \frac{1}{(n-1)^2}\frac{\operatorname{vol}(S_1^{n-2})}{(n-2)!\,\omega_{n-2}} = \frac{\sigma_{n-2}}{(n-1)^2\,(n-2)!\,\omega_{n-2}}\\
&= \frac{\frac{n-1}{2\pi}\sigma_n}{(n-1)(n-1)!\,\frac{n}{2\pi}\omega_n} = \frac{\sigma_n}{n!\,\omega_n} = \frac{\operatorname{vol}(S_1^n)}{n!\,\omega_n}.
\end{aligned}$$

The result follows by induction after checking the base cases, $n = 1$ and $n = 2$, using $\sigma_1 = 2\pi$, $\omega_1 = 2$, $\sigma_2 = 4\pi$ and $\omega_2 = \pi$. ☐

We will see in the next section that the leading term in the asymptotic expansion of the magnitude of any homogeneous is of this form. In [6] and [11] we gave a precise conjecture for the asymptotic behaviour of the magnitude of 'nice' subsets of Euclidean space and this involved the being asymptotically the same as the 'penguin valuation' defined for X a subset of Euclidean space as

$$P(X) := \sum_i \frac{\mu_i(X)}{i!\,\omega_i}$$

We are here considering the sphere with its intrinsic metric so it is not a metric subspace of Euclidean space, but the leading term and constant term we obtain are the same as for in the penguin valuation. However, the subdominant term is different. We would expect $\mu_{n-2}(S_R^n)/((n-2)!\,\omega_{n-2})$ but we get the following: it can be proved inductively as the formula for the leading term was in the above theorem, it is also a consequence of the theorem in the next section on general homogeneous Riemannian manifolds.

Theorem 9. *The first non-trivial, subdominant term of $P(S_R^n)$ is given by*

$$\frac{(n+1)}{3(n-1)}\frac{\mu_{n-2}(S_R^n)}{(n-2)!\,\omega_{n-2}}.$$

These results are compared with analogous ones for the magnitude of the n-sphere with the subspace metric in Section 5.

4 Asymptotics for homogeneous Riemannian manifolds

In this section we will look at the three leading terms in the asymptotics of the magnitude of a homogeneous Riemannian manifold, as the manifold is scaled up. The leading term will be seen to be proportional to the volume of the manifold, the second-leading term will be seen to be zero and the third-leading term will be seen to be proportional to its total scalar curvature, or in other words the top two leading terms are proportional to the top two intrinsic volumes. In particular, for a homogeneous surface Σ, the magnitude is asymptotically $\frac{1}{2\pi}\operatorname{area}(\Sigma) + \chi(\Sigma)$, and this is precisely the evaluation of the functional from [6].

By Speyer's Homogeneous Magnitude Theorem (Theorem 1) we know that the magnitude of a homogeneous Riemannian manifold X is given by

$$|X| = \frac{\int_X \mathrm{dvol}}{\int_X e^{-d(x,x_0)}\mathrm{dvol}}.$$

If we look at this as we scale up the space we should consider

$$|tX| = \frac{\int_{tX} \mathrm{dvol}}{\int_{tX} e^{-d(tx,tx_0)}\mathrm{dvol}} = \frac{t^2\int_X \mathrm{dvol}}{t^2\int_X e^{-td(x,x_0)}\mathrm{dvol}} = \frac{\int_X \mathrm{dvol}}{\int_X e^{-td(x,x_0)}\mathrm{dvol}}.$$

We wish to consider the asymptotics of the denominator $\int_X e^{-td(x,x_0)}\mathrm{dvol}$. The relevant piece of asymptotic analysis we will require is a version of Watson's Lemma (see for example [7]).

Theorem 10 (Watson's Lemma). *If $g\colon [0,c] \to [0,\infty)$ is a bounded function which, for some $N > 0$, has an expansion*

$$g(r) = \sum_{i=0}^{N} \alpha_i r^i + O(r^{N+1}) \qquad \text{as } r \to 0$$

then

$$\int_0^c e^{-tr} g(r)\mathrm{d}r = \sum_{i=0}^{N} \frac{i!\,\alpha_i}{t^{i+1}} + O(t^{-N-2}) \qquad \text{as } t \to \infty.$$

□

The idea behind Watson's Lemma is that as a function of $r \in [0,c]$, when t gets larger and larger e^{-tr} looks more and more like a function supported on a smaller and smaller neighbourhood of $r = 0$, so the integral will, up to exponentially small corrections, only depend on the germ of g near $r = 0$.

This can now be used to identify the leading asymptotics of the magnitude for homogeneous manifolds.

Theorem 11. *If X is an n-dimensional homogeneous Riemannian manifold and* tsc *denotes total scalar curvature then as X is scaled up the asymptotics of the magnitude are as follows:*

$$\begin{aligned} |tX| &= \frac{1}{n!\,\omega_n}\Big(\operatorname{vol}(tX) + \frac{n+1}{6}\operatorname{tsc}(tX) + O(t^{n-4})\Big) \\ &= \frac{\mu_n(X)}{n!\,\omega_n} t^n + \frac{(n+1)\,\mu_{n-2}(X)}{3(n-1)!\,\omega_{n-2}} t^{n-2} + O(t^{n-4}), \quad \text{as } t \to \infty. \end{aligned}$$

Proof. The idea is to pick a point $x_0 \in X$ and define the coordinate $r(x) = d(x, x_0)$. Let F_r be the set of points at a distance r from x_0, then if τ denotes the scalar curvature of X, which will be the same at every point, then we know

$$\mathrm{vol}_{n-1}(F_r) = \sigma_{n-1} r^{n-1}\Big(1 - \frac{\tau}{6n} r^2 + O(r^4)\Big) \qquad \text{as } r \to 0.$$

Because r parametrizes distance, locally the volume form splits as $\mathrm{dvol}_{F_r}\,\mathrm{d}r$. We can write D for the diameter of X. Then we find, using Watson's Lemma appropriately,

$$\begin{aligned}\int_X e^{-td(x,x_0)}\mathrm{dvol} &= \int_{r=0}^{D}\int_{F_r} e^{-tr}\mathrm{dvol}_{F_r}\,\mathrm{d}r = \int_{r=0}^{D} e^{-tr}\,\mathrm{vol}(F_r)\,\mathrm{d}r \\ &= \sigma_{n-1}\Big(\frac{(n-1)!}{t^n} - \frac{(n+1)!\,\tau}{6nt^{n+2}} + O(t^{-n-4})\Big) \quad \text{as } t \to \infty \\ &= \frac{n!\,\omega_n}{t^n}\Big(1 - \frac{(n+1)\tau}{6t^2} + O(t^{-4})\Big),\end{aligned}$$

where in the last equality we have used the fact that $\sigma_{n-1} = n\omega_n$. Thus we get

$$\begin{aligned}|tX| &= \frac{\int_X \mathrm{dvol}}{\int_X e^{-td(x,x_0)}\mathrm{dvol}} = \frac{t^n \int_X \mathrm{dvol}}{n!\,\omega_n\Big(1 - \frac{(n+1)\tau}{6t^2} + O(t^{-4})\Big)} \\ &= \frac{1}{n!\,\omega_n}\Big(t^n \int_X \mathrm{dvol} + \frac{n+1}{6} t^{n-2}\int_X \tau\,\mathrm{dvol} + O(t^{n-4})\Big) \quad \text{as } t \to \infty \\ &= \frac{1}{n!\,\omega_n}\Big(\mathrm{vol}(tX) + \frac{n+1}{6}\,\mathrm{tsc}(tX) + O(t^{n-4})\Big).\end{aligned}$$

This gives the first description of the asymptotics, to get the second it is just necessary to recall that $\mu_{n-2}(X) = \frac{1}{4\pi}\,\mathrm{tsc}(X)$ that $\mu_{n-2}(tX) = t^{n-2}\mu_{n-2}(X)$ and that $\omega_n = \frac{2\pi}{n}\omega_{n-2}$. ☐

This theorem immediately gives the asymptotics of the magnitude of a homogeneous surface, by taking $n = 2$ in the above and noting that μ_0 is precisely the Euler characteristic χ.

Corollary. *For Σ a homogeneous Riemannian surface, the magnitude is asymptotically given in terms of the area and the Euler characteristic by*

$$|t\Sigma| = \frac{\mathrm{area}(t\Sigma)}{2\pi} + \chi(t\Sigma) + O(t^{-2}) \qquad \textit{as } t \to \infty.$$

It is interesting to note that in the examples we know of, namely for spheres and surfaces, the constant term in the asymptotic expansion of the magnitude is precisely the Euler characteristic.

5 The subspace metric on the sphere

In this section we look at the metric on the n-sphere obtained by thinking of it as sub-metric space of $\mathbb{R}^{n+1}$ via the standard embedding. An explicit formula is given for the magnitude of the 2-sphere with this metric, whereas for $n > 2$ just the leading few terms of the asymptotic expansion are given. This is sufficient to see that the leading term is the same as for the magnitude of the sphere with the intrinsic metric but that the lower order terms are not the same.

In [6] we showed that equipping the radius R *circle* with the intrinsic metric and the subspace metric gave rise to different magnitudes, but that asymptotically the magnitudes differed by a vanishingly small piece:

$$\left|S^1_R\right|, \left|S^1_{\mathrm{sub},R}\right| = \pi R + O(R^{-1}) \quad \text{as } R \to \infty.$$

With the techniques so far developed in this paper it is not difficult to calculate the magnitude of the 2 sphere with these two metrics and see that only the leading term in the asymptotic expansion are the same.

Theorem 12. *For the* 2*-sphere of radius* R *with the subspace metric the magnitude is given by*

$$\begin{aligned}\left|S^2_{\mathrm{sub},R}\right| &= \frac{2R^2}{1-e^{-2R}(1+2R)} \\ &= 2R^2 + O(R^{-1}) \quad \textit{as } R \to \infty.\end{aligned}$$

For the 2*-sphere of radius* R *with the intrinsic metric the magnitude is given by*

$$\begin{aligned}\left|S^2_R\right| &= \frac{2R^2+2}{1-e^{-\pi R}} \\ &= 2R^2 + 2 + O(R^{-1}) \quad \textit{as } R \to \infty.\end{aligned}$$

Thus the sub-leading terms of the asymptotic behaviour are different for the two different metrics.

Proof. The intrinsic metric result is in Theorem 7, so it is just necessary to do the calculation for the subspace metric. This is analogous to the calculation for the intrinsic metric. By the Homogeneous Magnitude Theorem

$$\begin{aligned}\left|S^2_{\mathrm{sub},R}\right| &= \frac{\int_{x\in S^2_R} \mathrm{dvol}}{\int_{x\in S^2_R} e^{-d_{\mathrm{sub}}(x_0,x)}\mathrm{dvol}} = \frac{4\pi R^2}{\int_{\theta=0}^{\pi} e^{-R2\sin(\theta/2)} 2\pi R\sin(\theta) R\,\mathrm{d}\theta} \\ &= \frac{2}{\int_{\theta=0}^{\pi} e^{-R2\sin(\theta/2)}\sin(\theta)\,\mathrm{d}\theta}.\end{aligned}$$

Using the substitution $s := 2\sin(\theta/2)$ gives the following evaluation of the integral:

$$\int_{\theta=0}^{\pi} e^{-R2\sin(\theta/2)}\sin(\theta)\,\mathrm{d}\theta = \int_{s=0}^{2} e^{-Rs} s\,\mathrm{d}s = \frac{1-e^{-2R}(1+2R)}{R^2}.$$

The result follows immediately. □

Whilst I don't know how to get a general closed form for the magnitude of the sphere with the subspace metric, using the techniques of the previous section it is straight forward to calculate the first few terms in the asymptotic expansion of the magnitude and compare them with those for the intrinsic metric.

Theorem 13. *For the n-sphere of radius R with the subspace metric the magnitude is given asymptotically by*

$$\left|S^n_{\mathrm{sub},R}\right| = \frac{\mathrm{vol}(S^n_R)}{n!\,\omega_n}\left(1+\frac{(n+1)n(n-2)}{8}R^{-2}+O(R^{-4})\right) \quad \text{as } R\to\infty.$$

For the n-sphere of radius R with the intrinsic metric the magnitude is given asymptotically by

$$\left|S^n_R\right| = \frac{\mathrm{vol}(S^n_R)}{n!\,\omega_n}\left(1+\frac{(n+1)n(n-1)}{6}R^{-2}+O(R^{-4})\right) \quad \text{as } R\to\infty.$$

Proof. The intrinsic metric result follows from Theorem 11 together with the fact from Section 2 that the scalar curvature of the n-sphere with radius R is $n(n-1)R^{-2}$.

For the subspace metric result, proceed as usual by using Speyer's Homogeneous Magnitude Theorem and writing σ_n for the volume of the unit n-sphere.

$$\begin{aligned}\left|S^n_{\mathrm{sub},R}\right| &= \frac{\int_{x\in S^n_R}\mathrm{dvol}}{\int_{x\in S^n_R} e^{-d_{\mathrm{sub}}(x_0,x)}\mathrm{dvol}} = \frac{\mathrm{vol}(S^n_R)}{\int_{\theta=0}^{\pi} e^{-R2\sin(\theta/2)}\sigma_{n-1}\big(R\sin(\theta)\big)^{n-1}R\,\mathrm{d}\theta} \\ &= \frac{\mathrm{vol}(S^n_R)}{\sigma_{n-1}R^n\int_{\theta=0}^{\pi} e^{-R2\sin(\theta/2)}\sin^{n-1}(\theta)\,\mathrm{d}\theta}.\end{aligned}$$

Again making the substitution $s := 2\sin(\theta/2)$ whilst noting that $\sin(\theta)\,\mathrm{d}\theta = s\,\mathrm{d}s$ and $\sin(\theta) = s\sqrt{1-s^2/4}$ the integral can be manipulated as follows:

$$\int_{\theta=0}^{\pi} e^{-R2\sin(\theta/2)}\sin^{n-1}(\theta)\,\mathrm{d}\theta = \int_{s=0}^{2} e^{-Rs}s^{n-1}(1-s^2/4)^{(n-2)/2}\mathrm{d}s,$$

so by the generalized Binomial Theorem,

$$= \int_{s=0}^{2} e^{-Rs}\sum_{i=0}^{\infty}(-1)^i\binom{\frac{n-2}{2}}{i}\frac{s^{n-1+2i}}{4^i}\,\mathrm{d}s$$

whence by Watson's Lemma, as $R\to\infty$,

$$\begin{aligned} &= \sum_{i=0}^{m}(-1)^i\binom{\frac{n-2}{2}}{i}\frac{(n-1+2i)!}{4^iR^{n+2i}} + O(R^{-n-2m+1}) \\ &= \frac{(n-1)!}{R^n}\left(1-\frac{(n-2)}{2}\,\frac{(n+1)!}{(n-1)!\,4}R^{-2}+O(R^{-3})\right).\end{aligned}$$

Substituting this back into the above formula gives the required result on recalling that $\sigma_n = n\omega_n$. ☐

One can think of this result as saying that just as the intrinsic and subspace metrics are infinitesimally the same in a certain sense — though I don't know the correct way to formalize that — so the corresponding magnitudes are asymptotically the same in a certain sense, namely $\left|S^n_R\right|/\left|S^n_{\mathrm{sub},R}\right|\to 1$ as $R\to\infty$, although they are not the same in a stronger sense because, in general, $\left|S^n_R\right| - \left|S^n_{\mathrm{sub},R}\right| \not\to 0$ as $R\to\infty$.
